Received 3 January 2020; accepted 9 July 2020

Abstract. The paper investigates the accidents and fatalities on the main road network in the North-West Region of Romania over a period of 4 years (2015–2018). The aim of the paper is to highlight some shortcomings and suggest possible improvements of the road network in order to reduce the number of accidents and fatalities. Detailed analyses, including statistical and spatial statistical analyses, were conducted on the accidents involving goods and public transport vehicles considering the scale of their impact. As a result, black corridors and vulnerable municipalities were identified. They were found to be related to the reduced main road density and high levels of freight traffic transit. In conclusion, with one of the lowest motorization rates in the EU and given the important efforts already made by the police, improving road network in Romania becomes the key for reducing accident and fatality rates in the region. In this regard, it is suggested that motorways and ring roads are needed in

order to bypass the vulnerable municipalities. The results of this research may enable planners and administrations to act strategically to improve road safety in the critical areas, to prioritize actions for road network development and to formulate better strategies to ensure road safety.

**Keywords:** Geographic Information System (GIS), goods vehicles, public transport vehicles, road safety, vulnerable municipalities.

**Introduction**

Road safety is an essential component of a modern transportation system. Efficiency of the system, including safety, implies a reliable road network with a certain density of the dedicated infrastructure for high-speed and goods vehicles. According to the European Commission (2019), Romania ranks first in the European Union in terms of road fatalities per million inhabitants in 2018, although the evolution over the period of time between 2010 and 2018 presents the same trend as the EU average. Improvements have been made in many areas by the authorities, especially by the Romanian Police. Traffic Department of the General Inspectorate of Romanian Police (TDGIRP) is also part of the CARE project (European Commission, 2018a). However, reducing fatalities on roads is a far more complex problem and road network development is the key issue in this matter.

The National Strategy for Road Safety for the period 2015–2020 (n. d.) specifies that there is no possibility to drastically reduce the number of victims of traffic accidents given the increasing motorization rate and mobility, while road network development is not being carried out at the same rate. The strategy mentions the reduced state of development of road network but none of the objectives addresses the need to increase road network density. At the same time, the need to increase the safety of goods and passenger transport, improving the norms regarding traffic analysis, the regulation of mobility plans, including road safety in the urban planning and spatial planning process are some of the important objectives that are mentioned in the document. An important problem which is highlighted in the strategy refers to urbanization along transit roads – European, national, and county roads, namely, the existing linear localities along them, but there is no recommendation to build ring roads or bypasses.

Previous road safety research in Romania has generally documented the connection between national roads and accident rates (Cadar, Boitor & Dumitrescu, 2017), vehicle-to-vehicle car crashes (Coșciug, Ciobanu & Benedek, 2017), spatial characteristics of road traffic accidents and injuries (Ciobanu & Benedek, 2015), as well as the correlation at the national level between the number of accidents and urbanization level.
Some analyses were conducted at the local level. Hotspots were determined in Cluj-Napoca (Romania) and they were used to classify dangerous street segments (Benedek, Ciobanu, & Man, 2016). Vulnerable areas within the city of Cluj-Napoca were identified based on the correlation between low-light conditions and the number of traffic accidents (Ivan, Haidu, Benedek & Ciobanu, 2015).

Goods vehicles (HGV and LGV) and public transport (PT) vehicles transporting a larger number of people run on these types of roads and they represent the main focus in the research, because accidents involving these types of vehicles tend to have a more severe impact and higher costs (Lindberg, 2006). For instance, in Sweden, per kilometre driven, HGV and buses killed five times as many car occupants as passenger cars did (Björnstig, Björnstig & Eriksson, 2008). Furthermore, road type is important in the analysis of commercial vehicle crashes as these tend to occur on the main roads (59%) (Kofalvi & Vincze-Pap, 2001).

In view of these preliminary observations, the paper aims to investigate the accidents and fatalities on the main road network in the North-West Region of Romania in order to highlight some shortcomings and suggest possible improvements to the road network in order to reduce the number of accidents and fatalities. The research focuses on LGV and HGV vehicles along with PT vehicles, highlighting that the low level of road network development is the key factor in accidents occurrence. Addressing the imperative need to improve the road network, the paper argues that the focus should be made on building appropriate infrastructure for high-speed and goods transport, such as motorways, expressways, ring roads, bypasses, and collector streets.

The main road network considered in the study consists of motorways, national and county roads. The black corridors spotted on these roads are seen as input data in analysing road safety issues in the region; they could be considered in the early stages of developing a planning strategy for improving road safety. The scope of the analysis conducted in this paper, namely, analysis at the regional level, provides new insight into road safety issues (Wachnicka, Kustra, Jamoroz & Budzynski, 2016). As a result, vulnerable municipalities or areas in the region are detected based on the spatial distribution, densities and hotspots of accidents and fatalities. Depending on the statistical relevance of the hotspots, three levels of vulnerability are used to classify the municipalities in the N-W Region of Romania. Therefore, efficient planning strategies can be implemented to improve road safety as long as interventions are prioritised based on the level of vulnerability. Prior actions should be taken by authorities in the deadliest municipalities or wider areas. This methodology was applied
in the first case study of N-W Region of Romania. It can be considered a simple but innovative and adequate solution for road safety analysis and identification of the critical areas. GIS (Geographic Information System) visualization tools can provide quick and sound information; it appeared useful for assessment of road safety issues. The results may enable administrations to prioritize the actions for road network development and planners and policy makers – to develop better road safety strategies.

The paper comprises the following sections: Introduction, Data and methods, Case study, Results and findings, and finally, Discussion and conclusions.

1. Data and methods

The data used in this research are taken from five main sources: Romania National Institute of Statistics, Eurostat, Traffic Department of the General Inspectorate of Romanian Police, OpenStreetMap, Romanian INSPIRE Geoportal.

Datasets from the Romania National Institute for Statistics (2018, 2019) and Eurostat (2017, 2019) were employed for the general overview of the transport system and socio-demographics in the N-W Region. The counties in the N-W Region were analysed based on the NIS data. They present specific details referring to population, areas, municipalities, motorization rate, road motor vehicle rate and aspects of the road network, which are extensively presented in the case study. The road network aspects, namely, the length and density, are presented in line with the aim of the research separately for motorways and express roads, national roads, regional roads and bypasses.

New data sets regarding road accidents in the North-West Region of Romania are available. These present specific details referring to locations, participants and vehicles involved in the accidents. Data collection is conducted by the Traffic Department of the General Inspectorate of Romanian Police, who provided the data for the period between 2015 and 2018 for this research in three different datasets regarding incident location, participants and vehicles. A total number of 14 244 accidents was recorded, out of which 2020 involved LGV, HGV or PT vehicles. The analysis focuses on the accidents involving goods and public transport vehicles.

Data analyses were performed using Excel. Statistical analyses were conducted using filters, selections and pivot tables in Excel on all three datasets regarding incident location, participants and vehicles. Firstly, vehicles were classified according to the purpose of this research into
heavy goods vehicles, light goods vehicles and public transport vehicles (busses, mini-busses, coaches, trolleybuses and trams) and others. Goods vehicles and passenger transport vehicles are all considered in the selection due to their load and respective scale of accidents. Vehicles were classified into these categories using such details as brand, model and intended use of the vehicle. If it was not clear whether the vehicle is specifically HGV, LGV or PT, it was not considered. Trailers were not considered either. The most important step in the research was to classify the vehicles according to the Romanian traffic norms, an aspect which was not considered in the data collection process at the time of accident registration. Therefore, the initial database of the accidents was not edited but some new fields were added for the purpose of this research. The most important statistical indicators of this research are accident rate (AR) and fatality rate (FR). AR was calculated as a percentage of the number of accidents that occurred in each county in the total number of accidents (Ciobanu & Benedek, 2015). AR was also obtained for specific conditions such as HGV, LGV or PT vehicles, location in or outside locality and by type of road. FR was calculated as a percentage of the number of deaths that occurred in each county in the total number of accidents (Pirotti, Guarnieri & Vettori, 2011). These indicators can be further used for comparison with the previous studies, which documented the data on the same areas.

GIS analyses were performed using ArcGIS platform. The database provided by TDGIRP was georeferenced. A total number of 13,995 georeferenced points were obtained. The accidents located outside the N-W Region were excluded. Furthermore, 2019 accidents involving HGV, LGV or PT vehicles were found in the N-W Region but only 1983 of these points had valid information to support the application of Join tool for connecting the accidents dataset with the vehicles dataset. Three types of analyses with specific tools were used: spatial distribution of the road network, accidents and victims, spatial density of accidents and fatalities, including kernel density of accidents and fatalities, and spatial statistics – average nearest neighbour, Global Moran I and hotspot analysis (Getis-Ord Gi*). Each type of analysis represents one step of the methodology developed in this paper. The proposed methodology has been applied in the first case study of N-W Region of Romania for both accidents and fatalities datasets. The accidents dataset is considered initially to provide some insights into the location of the incidents. Firstly, the spatial distribution of the accidents is used. The simple method helps visualize the accidents by location in order to establish black corridors and to summarize accidents in the municipalities and counties. Secondly, spatial densities are obtained. Heat maps are created, since they are a simple but effective visual tool. Moreover, kernel density interpolation is used. Euclidian kernel density was established based on the results of the Average Nearest Neighbour analysis, which is a
spatial statistics tool used in this research. An observed mean distance was 1154 m, and experience from the previous research called for using two search radiuses of 1000 m and 6000 m (Thakali, Kwon & Fu, 2015). Obvious differences were established for the two values of the search radius in terms of density, but they confirmed the initial results obtained in the heat maps. Furthermore, they helped formulate the alternative hypothesis that accidents do form spatial clusters in the region for the spatial statistical analysis. Thirdly, the pattern was validated with Global Moran I and Hot Spot analysis (Getis-Ord Gi*). The results of the Global Moran analysis indicated a strong spatial autocorrelation of the accidents. This allowed conducting a more complex pattern analysis within the hotspot analysis. Accident hotspots were identified. They provide a statistically relevant result concerning the critical areas in the region where accident clusters occur. The same three-step methodology was applied to the study of fatalities. Spatial distribution and densities, as well as spatial statistics, were used to identify the vulnerable municipalities or wider areas in the region where more fatal accidents occur.

OpenStreetMap (n. d.) and Romanian INSPIRE Geoportal (n. d.) provided the layers for the GIS representation, the road network and administrative limits in the N-W Region, respectively.

2. Case study

Romania is a large country with four first-level NUTS regions (Macroregions, Figure 1a) including eight second-level NUTS regions (Regions, Figure 1b). The study focuses on the North-West Region of Romania (N-W Region), which includes 6 counties: Bihor (BH), Bistrița-Năsăud (BN), Cluj (CJ), Maramureș (MM), Satu Mare (SM) and Sălaj (SJ) (Figure 1c).

Figure 1. The North-West Region of Romania: a) Macroregion 1; b) regions; c) counties of the region
2.1. Aspects of the road transportation system

All three components of the road transportation system in the region are documented – people or users, vehicles and road network – for all six counties: BH, BN, CJ, MM, SM and SJ. The N-W Region has a total population of 2,556,639 inhabitants and a total area of 34,160 km$^2$ as described in Table 1 (Romania National Institute for Statistics, 2019). There are 1,911 municipalities in the region, out of which 15 are cities, 28 towns, and 403 communes. CJ has the largest population among the counties of this region, it also has the highest density of population of 106 inh/km$^2$. BH comes second after CJ in terms of number of residents. The population density in BH is similar to that in SM, MM and the average value in the region. BH and CJ have a larger number of municipalities compared to the other counties. The motorization rate in CJ is 357 cars per 1000 inhabitants, which is not very high compared to BH, which comes second with a motorization rate of 341 cars per 1000 inhabitants. The motorization rate in the N-W Region with 333 cars per 1000 inhabitants is almost equal to the national rate (Romania National Institute for Statistics, 2019). In this respect, Romania comes last in the EU (Eurostat, 2017). When considering road motor vehicles per 1000 inhabitants, the N-W Region demonstrates a slightly higher rate than the national one. Note: * values reported by the NIS.

Figure 2. The motorways and bypasses in the N-W Region of Romania, 2019

The motorization rate in the N-W Region has increased over the study period, from 261 to 333 cars per 1000 inhabitants, road network density did not vary significantly, increasing by 59 km in the total length (Romania National Institute for Statistics, 2019).
Table 2 presents the data on the road network summarized by the Romania National Institute for Statistics (2018). The road network includes all roads in the N-W Region: motorways and express roads, national roads, regional or county roads, and other urban and rural or local roads. According to the Romanian norms, streets are considered differently from roads. The length of the national roads in CJ is 566 km, followed closely by BH with 528 km. CJ is the only county that has an operational motorway with a length of 68 km. There are no express roads in the region. According to Government Decision No. 782 (The Government of Romania, 2014), not a single city or town in the N-W Region has a ring road. However, Cluj-Napoca (CJ), Gherla (CJ) and Oradea (BH) have some bypasses that run outside the localities and Bistrița (BN) and Ștei (BH) have some links, which are named bypasses but they run throughout the localities passing by the central area. In total, 9 out of 43 cities and towns in the N-W Region have bypasses, with a total length of 109 km. The motorways and bypasses in the N-W Region in 2019 are illustrated in Figure 2. According to Knoema (n. d.), road density is the ratio of the length of the country’s total road network to the country’s land area. Road density in the N-W Region is very close to the national value of 36 km per 100 km². Although the road network density and motorway density in the N-W region is slightly above the national value, they are still very low.

2.2. Road accident-related aspects

During the 4-year period, between 2015 and 2018, TDGIRP recorded 14,244 accidents in the N-W Region. It resulted in 5.6 accidents per 1000 people. In total, 21,702 vehicles and 19,172 people were involved in all accidents, resulting in 964 fatalities. Table 3 presents an overview of the initial statistical analysis. It provides insights into the type and number of vehicles involved in the accidents, incidence of events by locality and type of road, and the number of fatalities. Table 4 presents accident and fatality rates for each county of the region. It shows that 34% of the accidents were registered in CJ. This percentage is four times higher than that of the county with the lowest number of accidents, namely, SM. Accidents involving HGV, LGV and PT vehicles were considered for a more detailed analysis. 13% of the accidents in the region involved at least one HGV, LGV or PT vehicle, 45% of the accidents occurred on the main road network, 81% of the accidents occurred inside a locality. CJ is the county with the highest AR. Some general observations on the material losses in accidents are related to the number of vehicles involved. A total of 3705 HGV, LGV, and PT vehicles were involved in

these accidents. 874 accidents involved at least two HGV, LGV, and PT vehicles. The maximum number of vehicles involved simultaneously in an accident with HGV, LGV or PT vehicles was none and the maximum number of HGV, LGV, and PT vehicles involved simultaneously in an accident was three.

3. Results and findings

A total number of 14,244 accidents were recorded in the North-West Region over the study period, between 2015 and 2018, out of which 2020 involved LGV, HGV or PT vehicles. The outcome of the accidents and fatality rates of the accidents involving HGV, LGV and PT vehicles by county presented in Table 5 show that 36% of the accidents involving HGV, LGV and PT vehicles were registered in CJ, 17% in BN, 17% in BH, 14% in MM, 6% in SM and 10% in SJ. The fatality rates follow a similar trend in the counties, namely, 3% in CJ and BH, 2% in BN, respectively, 1% in MM, SM and SJ. The statistical analysis of the accidents involving LGV, HGV and PT shows that these accidents mainly occurred

Figure 3. Accidents involving HGV, LGV and PT vehicles in the N-W Region between 2015 and 2018: a) incidence by type of road; b) incidence in or outside a locality.
within built-up areas of localities and along the main road network (Figures 3a, 3b; Table 5). The highest fatality rate was recorded in CJ and BH.

A total number of 13,995 points were georeferenced, out of which 2019 points were accidents involving HGV, LGV or PT. Only 1983 of these points had valid information to support the Join tool for connecting the accidents dataset with the vehicles dataset. The methodology, which was developed and applied for the case study, involved conducting three types of GIS analysis, namely spatial distributions, spatial densities and spatial statistics, for both accidents and fatalities datasets. GIS analyses were performed using spatial distribution of the road network, accidents and victims, spatial density of accidents and fatalities, including kernel density of accidents and fatalities and spatial statistics - average nearest neighbour, Global Moran I and hotspot analysis (Getis-Ord Gi*).

Firstly, the spatial distribution of the accidents helps to visualize the accidents by location and to establish the black corridors in the N-W Region.

The map presented in Figure 4a shows the location of accidents involving HGV, LGV and PT vehicles, validates the numerical data presented previously in the charts and tables, and provides a perspective on the black corridors in the N-W Region.

Secondly, spatial densities are obtained using the heat map and kernel density interpolation tools.

Figure 4b presents the results of the kernel analysis, it validates the presence of black corridors in the first map. The analysis was conducted using a round value of 1000 m for the search radius, which is very close to the observed mean distance of 1154 m that resulted from the Average Nearest Neighbour analysis. A maximum density of 1.14 accidents per cell was obtained.

Summing up the accidents in municipalities shows the vulnerable municipalities with higher accident incidence. This helps identify the critical areas in the N-W Region. Figures 5a and 5b present the two sides of the same coin, namely, a sum of the accidents involving HGV, LGV and PT vehicles within municipalities against their heat map. Kernel analysis was conducted using a search radius of 6000 m, namely, six times the closest round value of the observed mean distance. The outcome of a maximum density of 4.35 accidents per cell is presented in Figure 5c.

Thirdly, the pattern was validated with spatial statistics indicators, such as Global Moran I and Hot Spot analysis (Getis-Ord Gi*). The Global Moran analysis of the accidents reported a value of 0.0591 for Global Moran’s Index, a Z-score of 4.606 and a p-value of 0.000004. The results indicate that there is a strong spatial autocorrelation of
Accidents involving HGV, LGV and PT vehicles in the North-West Region of Romania: a) location on the main road network; b) kernel density estimation of road accidents involving HGV, LGV and PT. This facilitated the hotspot analysis. Accident hotspots were identified (Figure 5d). Hotspot analysis was conducted to provide a statistically relevant result concerning the critical areas in the region where accident clusters occur. The accident hotspots are clustered in the metropolitan area of Cluj-Napoca (red cells in Figure 5d). The regional urban centre of Cluj-Napoca is the most vulnerable city and the hotspots clustered around the city are the most vulnerable municipalities in the region.
Every accident has a negative impact, particularly in terms of the lost lives. In total, 238 lives were lost between 2015 and 2018 in the N-W Region in the accidents involving HGV, LGV and PT vehicles, which represented 25% of the total fatalities in the region. The percentage is higher than the 16–18% of fatalities resulting from accidents involving HGV busses and coaches registered within the EU in the period between 2007 and 2016 (European Commission, 2018b). Although the number of fatalities (238 people) is lower than that of severely injured (787 people) and slightly injured (1750 people), still those lives are lost.
Figure 6. Victims of HGV, LGV and PT accidents in the N-W Region over the period between 2015 and 2018: a) fatalities, seriously injured and slightly injured summarized in the municipalities; b) fatalities, seriously injured and slightly injured summarized in the counties; c) fatalities heat map; d) fatalities kernel density; e) fatalities hotspots and cold spots.
The impact of accidents involving LGV, HGV and TP on traffic conditions remains an important factor, especially since accident localities are concentrated in the urban areas and along the national roads, given the extremely high density of linear municipalities along these roads (Figure 6a). This aspect may be considered in more detail when comparing the results of the summarization per municipality to those of the summarization per county (Figure 6b). Moreover, the descending trend of the lives lost in these accidents, namely, 62 in 2015, 59 in 2016 and 52 in 2017 changed to 65 deaths in 2018. The fatalities heat map in Figure 6c shows a similar picture to the accidents heat map. The kernel density of the fatalities is presented in Figure 6d. A maximum density of 5.45 accidents per cell was obtained using a search radius of 6000 m. The pattern was validated with spatial statistics indicators, such as Global Moran I and Hot Spot analysis. The Global Moran analysis of the fatalities reported a value of 0.082586 for Global Moran’s Index, a Z-score of 4.086 and a p-value of 0.000044. The results indicated a strong spatial autocorrelation of the fatalities. This allowed conducting a more complex pattern analysis within the hotspot analysis. Fatalities hotspots were obtained (Figure 6e) to provide a statistically relevant result concerning the critical areas and to identify the vulnerable municipalities or wider areas in the region where more fatalities are registered. Fatalities hotspots show that critical areas are found in important urban municipalities and wider areas clustered around them. It is the case of the metropolitan area of Oradea located near the border, the regional pole of Cluj-Napoca and some linear municipalities situated on the main road network in BN. However, some municipalities demonstrate a totally different situation, an opposite trend highlighted by the cold spots, which present a desirable goal – statistically relevant safe areas.

**Discussion and conclusions**

The paper investigates the accidents and fatalities on the main road network in the North-West Region of Romania over the period of 4 years (2015–2018). Since 964 people died on the roads of the N-W Region of Romania between 2015 and 2018, there is an urgent need to act to improve road safety in order to reduce the social costs of accidents.

The transport system in the region is extensively documented in terms of people, vehicles and road network for all six counties: BH, BN, CJ, MM, SM and SJ. The N-W Region has a total population of 2 556 639 inhabitants and a total area of 34 160 km². Population is the largest and demonstrates the highest density in CJ. BH comes second
after CJ in terms of the number of residents. The population density in BH is similar to that in SM, MM and the average value in the region. BH and CJ have a larger number of municipalities compared to the other counties. The motorization rate is comparable among the counties. With 333 cars per 1000 inhabitants in the N-W Region, the motorization rate is almost equal to the national rate, it is one of the lowest in the EU. The length of the main road network in the region is reduced, the only operational motorway has a length of 68 km, there are no express roads and not a single city or town has a ring road.

These data were analysed along with the road accidents database provided by TDGIRP consisting of three datasets regarding incident location, participants and vehicles. The complex accidents database, which provides foundation for this research, was provided by TDGIRP, which has already made many improvements to increase road safety.

Accident and fatality rates were calculated and explicitly presented. Detailed analyses, including statistical and spatial statistical analyses, were conducted on the accidents involving goods and public transport vehicles due to the scale of their impact.

As a result, the highest number of accidents as well as that of fatalities was mostly found along the main roads and in the built-up areas of municipalities. Practically, this is related to the reduced road density and high levels of freight traffic transit in the populated areas. One solution to this problem would be to increase road density by building motorways or ring roads that bypass the localities. Furthermore, limiting the expansion of the urban areas along the existing roads by imposing restrictions in the urban planning documents may also be part of the solution. Without these measures and in the absence of an urban development strategy, there is a risk that by expanding linear municipalities, an even greater share of national roads will become mixed-function links, offering both mobility and local accessibility and thus reduced road safety because of traffic conflicts and low average speeds.

In conclusion, given one of the lowest motorization rates in the EU and the important efforts already made by the police, improvement of the road network in Romania becomes the key to reducing accidents and fatalities in the region.

Spatial distribution concepts, such as location of points on the map, summarization and other aggregation tools, heat maps, kernel density are useful for the administrations, although experts might see them as simple, subjective and perceptive models. This could be the case of simple heat maps, which are merely simple spatial distribution maps, which nevertheless help non-experts to easily spot critical areas. Simple spatial distribution tools are an elementary but powerful tool
for any party involved in the planning process. Considering the size of the region's area, it was observed that kernel analysis using a search radius of 6000 m, six times the value of the observed mean distance, resulted in an outcome which was more relevant for highlighting clustering trends. For further kernel density analyses, an even greater value of the cell size should be used, a more representative value of the observed mean distance multiplier in relationship with the length of the network and size of the area under study.

As a result, black corridors and vulnerable municipalities were identified.

The results of the Global Moran analysis indicated a strong spatial autocorrelation of the accidents and fatalities. This allowed conducting a more complex pattern analysis within the hotspot analysis. Hotspots were identified for both accidents and fatalities. They provide a statistically relevant result concerning the critical areas in the region where accident clusters and fatality clusters occur. The regional urban centre of Cluj-Napoca is the most vulnerable city, according to the results of the accidents hotspot analysis. The accidents hotspots are clustered around the city, including the municipalities in the metropolitan area of Cluj-Napoca. These critical areas with many accidents involving HGV, LGV and PT vehicles need reconfiguration of the road network. Local, regional and national administrations should focus on these areas. The shortcomings of the road network include low density, lack of motorways, express roads and bypasses that ultimately result in accidents with enormous social and material costs. A clear example in this respect is the number of victims involved in road accidents, and especially the number of fatalities. More critical areas are identified based on the results of the fatalities hotspot analysis. The fatalities hotspots are more numerous compared to the accidents hot spots, the results of their analysis open two different perspectives. On the one hand, the level vulnerability appears to be more gradual among municipalities, as different levels of confidence hotspots are revealed by the analysis. Fatalities hotspots show that critical areas are found in important urban municipalities and wider areas clustered around them. It is the case of the metropolitan area of Oradea located near the border, the regional pole of Cluj-Napoca and some linear municipalities situated on the main road network in BN. On the other hand, some municipalities demonstrate a totally different situation, an opposite trend highlighted by the cold spots, which present a desirable goal – statistically relevant safe areas.

Based on the results of the fatalities hotspot analysis, a municipality could be classified according to the road’s potential level of danger considering the reliability level of the pattern. Therefore,
the most relevant hotspots (99%) define the most critical areas, named extremely dangerous municipalities. This is the case of the metropolitan area of Oradea and Cluj-Napoca with the municipalities clustered around it (red cells in Figure 6e). Relevant hotspots (95%) define very critical areas, named very dangerous municipalities. This is the case of municipalities located in the proximity of the metropolitan area of Oradea and of Cluj-Napoca and some of them are linear municipalities, especially in BH, CJ and BN county, located on the main road network (orange cells in Figure 6e). Critical areas are defined by hotspots (90%) and named dangerous municipalities. These are some linear municipalities located on the main road network (yellow cells in Figure 6e). Therefore, the urgency for intervention has been highlighted along setting priorities for improvements of the road transport network to reduce the number of lives lost every year. These envision construction of new motorways, expressways, ring roads, bypasses, and collector streets in the municipalities, especially cities and linear municipalities.

Furthermore, the results of this research may enable the planners and administrations to act strategically for improving road safety in the critical areas, to prioritize the actions for road network development and to formulate better strategies in road safety.

Based on the results of the research, the future version of The National Strategy for Road Safety should include a specific objective in order to state the need for an improved road network. In this respect, improving the transportation system in the region should be carried out through the development of a reliable road network, which implies higher road density and dedicated infrastructure for high-speed and goods vehicles. In addition to road network improvements, the document should also consider the need for appropriate facilities for goods and passenger road transport, which are also very important factors for the drivers and could help increase the safety of goods and passenger transport.

According to the findings presented in the paper, another specific objective in the strategic plan should also refer to reviewing the planning and urban development norms, as well as including details referring to urbanization along the main transit roads – European, national, county – to limit the linear development of the existing municipalities along these. In this respect, it is necessary to restrict construction in the areas adjacent to the transit and bypass arteries. Care should be taken to avoid situations where bypasses and ring roads become local and access roads through the development of adjacent urban areas. Therefore, improving the road network by building appropriate infrastructure for high-speed and goods transport should
improve road safety and result in the reduction of both social and material costs in a holistic way, in an integrated planning process.

The paper has presented the first attempt to develop a methodology to study road safety at the regional level in Romania. It presented the statistical analyses and GIS analyses conducted within the case study. The complex accidents database, which provided the basis for this research, could be improved to include such variable as vehicle category according to the Romanian traffic norms in the characteristics recorded in the data collection process conducted at accident sites.

As a further step of this research, it is important to establish a specific correlation between traffic volume and accidents or fatalities. A different administrative level should also be considered in the future analysis with the focus on municipalities in order to establish the relationship between such variables as road network density, accident rate, fatality rate, traffic volumes, etc.
